Two changes made to the optics of the CHRNS 30-m SANS instrument during the installation of the NCNR’s new cold source have increased the flux at the sample and the low-\(Q\) resolution of the instrument. The increase in flux, over and above that provided by the new cold source, comes from replacing the instrument’s cooled bismuth-beryllium filter with an “optical filter” of the type shown schematically in Fig. 1. The optical filter replaces 10 m of straight neutron guide and its 40 cm long Bi-Be filter with an inclined guide section with a high critical angle supermirror reflective coating. The optical filter channels cold neutrons, with wavelengths as short as 3 Å, out of the line-of-sight of fast neutrons and gamma rays from the source. The cold neutrons delivered to the SANS instrument undergo an even number of reflections in the optical filter to emerge in the horizontal direction, but displaced 14 cm vertically. To accommodate the beam displacement, the entire SANS instrument had to be raised; a non-trivial task that required detailed engineering analysis, careful planning and skilled execution.

The design of the optical filter was refined with the aid of detailed Monte Carlo calculations of the angular and spectral distribution of neutrons transmitted by the optical filter. Figure 2 shows the calculated and measured gain in flux at the sample, due to the optical filter alone, for the supermirror reflectivity model shown in the inset. These results demonstrate that the optical filter transmission is about the same as the previous crystal filter for wavelengths around 5 Å, but becomes substantially better at longer wavelengths where absorption in the crystal filter becomes significant.

The optics for the CHRNS SANS instrument were further improved by installing a system of refracting lenses and prisms near the sample position to focus 17 Å neutrons onto the detector at its maximum distance, 13 m, from the sample. A similar lens system, consisting of 28 biconcave single crystals of MgF\(_2\) for focusing 8 Å neutrons, has been in use on the NCNR’s other 30-m SANS instrument on guide NG-7 for nearly two years [1]. The refracting power of the lenses increases with the wavelength squared, but so does the distance the neutron falls between the sample and detector due to gravity. The vertical spreading of the focus for a beam with a wave-
length spread typical of a SANS instrument, about 10 % to 15 % FWHM, restricts the utility of the lenses alone to wavelengths less than 10 Å. The new development implemented on the CHRNS SANS instrument is to follow the lenses with prisms that refract in the vertical direction to counteract the effect of gravity.

Figure 3 depicts the arrangement of lenses and prisms now installed on the CHRNS SANS instrument. Seven MgF₂ biconcave lenses focus 17 Å neutrons at the detector, 13 m from the sample. For this distance a single prism with an apex angle of 161° would cancel the beam spreading due to gravity for all wavelengths [2]. Such a prism, however, would have to be 250 mm long at its base to intercept the full beam height transmitted by the lenses (= 2 cm). A more practical scheme, as shown in Fig. 3, is to stack two sets of prisms, with each prism 30 mm long and 5 mm high with an apex angle of 143°, to give the same anti-gravity effect. In this scheme, the bottoms of each prism are coated with Gd₂O₃ to eliminate surface reflections.

The effectiveness of the lens/prism combination can be seen in Fig. 4 that compares circularly averaged SANS data from voids in an irradiated crystal of aluminum obtained with pinhole collimation and with the focusing optics. The data for the lens/prism system extend to a minimum scattering vector \( Q = 0.00045 \, \text{Å}^{-1} \), nearly a factor of two lower than the pinhole collimation. Furthermore, the scattered intensity is 3 times higher with the lens/prism system because a larger area of the sample can be illuminated without degrading the \( Q \)-resolution. With pinhole collimation, intensity at the detector is roughly proportional to \( Q_{\text{min}}^4 \), hence the lens/prism system represents an overall intensity gain of 48 compared with simply reducing pinhole aperture size to achieve the same minimum \( Q \).

The new cold source and improvements in optics are enabling microstructural studies that link nanoscale with microscale features in, for example, polymer-clay nanocomposites, gels, and fluxoid lattices in superconductors.
